## 1 Abstract

2 A comparative study of forest clear-cut logging effects on daily growing season (May to  
3 October) net ecosystem CO<sub>2</sub> exchange (*NEE*) of adjacent peatlands was conducted in two  
4 neighbouring forest upland-peatland complexes over four-years (2005 to 2008) on the Boreal  
5 Plains (BP) of Alberta, Canada. Higher vapour pressure deficit at the harvested-upland (H-U)  
6 peatland, reflecting increased turbulent mixing after adjacent upland forest removal (2007 and  
7 2008), resulted in increased peatland evapotranspiration rates that contributed to a seasonal  
8 decline in soil moisture (*VMC*) influencing *NEE*. Overall, a significant change in mid-season  
9 *NEE* occurred at the H-U peatland one-year post-harvesting, greater than *NEE* changes at the  
10 neighboring intact-upland peatland. However, two years post-harvesting, mid-season *NEE*  
11 returned to within range of pre-harvesting variability (-0.54 to 1.34 g CO<sub>2</sub>-C m<sup>-2</sup> d<sup>-1</sup>). Results of  
12 this study demonstrate that BP peatland *NEE* is largely regulated by site-specific water  
13 availability, which in turn, may be influenced in the short-term by shifting microclimate and soil  
14 moisture patterns due to clear-cut logging. As such, predicting long-term carbon storage function  
15 of BP peatlands will require careful consideration of changing hydroclimatic conditions due to  
16 rapid expansion of BP deforestation, given that these ecosystems already exist in a state of  
17 hydrologic risk in this moisture deficit eco-region.

1     **Introduction**

2     Peatlands and wetlands cover up to 50% of the land surface on the Boreal Plains (BP) and store a  
3     significant portion of carbon in Canada (Timoney, 2003; Kuhry *et al.*, 1993). The BP of western  
4     Canada is experiencing extensive deforestation by timber harvesting (clear-cut) as well as road  
5     and corridor construction from industrial oil and gas expansion (Timoney, 2003). Forests  
6     regulate the microclimatic and hydrologic conditions (incoming solar radiation, wind velocity,  
7     turbulence, temperature and moisture of the air and soils) of edge and adjacent ecosystems (Chen  
8     *et al.*, 1993; Flesch and Wilson, 1999; Petrone *et al.*, 2007; Markfort *et al.*, 2014). Rapid  
9     harvesting of upland forests may threaten the hydroclimatic stability of the already  
10    hydrologically tenuous adjacent peatland ecosystems on the BP (Solondz *et al.*, 2008; Brown *et*  
11    *al.*, 2010). While BP forest disturbance research has focused primarily on harvested areas and  
12    the associated water and carbon dynamics of the disturbed forest soils (e.g. Amiro *et al.*, 2006;  
13    Petrone *et al.*, 2015; Whitson *et al.*, 2005; Carrera-Hernández *et al.*, 2011), the potential impacts  
14    on the terrestrial-atmosphere exchange of water and carbon dioxide (CO<sub>2</sub>) in adjacent peatlands  
15    remains unknown. Given the importance of peatlands for BP carbon storage and water supply  
16    (Ferone and Devito, 2004; Smerdon *et al.*, 2005; Solondz *et al.*, 2008;), understanding how these  
17    peatlands respond to upland clear-cut logging is fundamental to improving the design and  
18    implementation of landscape management and forestry practices across this eco-region (Johnson  
19    and Miyanishi, 2008).

20    Previous studies examining carbon exchange in peatlands show that soil temperature and  
21    moisture conditions are well coupled to carbon losses (plant respiration and soil decomposition)  
22    and carbon uptake (plant productivity) at both the plot-scale and ecosystem-level (Solondz *et al.*,  
23    2008; Bubier *et al.*, 1998, 2003; McNeil and Waddington. 2003; Petrone *et al.*, 2011). The net

balance between CO<sub>2</sub> uptake and release (Net Ecosystem Exchange, *NEE*) is generally highest (i.e. increased net CO<sub>2</sub> release) under the most favourable conditions for microbial decomposition (i.e. warm, low moisture oxic peat) (Solondz *et al.*, 2008; Bubier *et al.*, 1998; Silvola *et al.*, 1996). Although the impact of land use changes on peatland water cycling and *NEE* are widely investigated in peatlands on the Boreal shield of eastern Canada (e.g. Waddington and Price 2000; Tuittila *et al.*, 1999), limited work on the response of peatland hydrology and/or trace gas exchange to anthropogenic disturbances exists on the BP of western Canada (Strack *et al.*, 2014). Heterogeneous glacial deposits along with the sub-humid climate of the BP, whereby precipitation roughly equaling potential evapotranspiration, results in water table positions and soil moisture gradients that are not under topographic control (Devito *et al.*, 2005). As such, it is unknown if shifts in peatland moisture conditions, soil temperature and carbon dynamics in response to disturbance events observed in the runoff-dominated shield can be extrapolated to peatlands in the complex hydrology of the sub-humid climate of the BP.

Forest cutblocks experience higher wind speeds, short-wave radiation, air temperatures and lower atmospheric moisture relative to within forest canopy stands (Chen *et al.*, 1993). Abrupt transitions between flat surfaces (e.g. cutblocks) and forest canopies or between vegetation types within a landscape can dynamically alter the atmospheric boundary layer and turbulent flow patterns across the transition zones (Markfort *et al.*, 2014; Yang *et al.*, 2006; Flesch and Wilson, 1999). As such, clear-cut logging has the potential to alter the microclimate conditions in adjacent peatlands to influence evapotranspiration (*ET*) and ecosystem water loss (Petrone *et al.*, 2007; Helgason and Pomeroy, 2005; Helgason and Pomeroy, 2012; Wharton *et al.*, 2010; Monteith, 1965). Given that subtle changes in *ET* can result in soil moisture deficits in this sub-humid climate (Devito *et al.*, 2005), shifts in *ET* are likely to be important to the CO<sub>2</sub> sink or

1  
2  
3 1 source status of BP peatlands. Due to the multitude of compounding hydrological interactions  
4  
5 2 and feedbacks in northern peatlands (Waddington *et al.*, 2015), applying an integrated  
6  
7 3 monitoring approach of hydrology, microclimate and CO<sub>2</sub> exchange is essential to evaluate the  
8  
9 4 natural baseline ecohydrological conditions of BP peatlands (e.g. Solondz *et al.*, 2008) and to  
10  
11 5 compare the potential impact of adjacent forest disturbance on the complex hydroclimatic and  
12  
13 6 biogeochemical factors governing peatland *NEE*.  
14  
15  
16  
17  
18 7 Long-term CO<sub>2</sub> exchange is coupled to atmospheric processes (Lafleur *et al.*, 1997). Increased  
19  
20 8 summer warming in recent decades observed in western Canada (Gullet and Skinner, 1992)  
21  
22 9 along with projections of rising global temperatures and greater drought frequency in Boreal  
23  
24 10 regions suggests a future reduction in CO<sub>2</sub> sequestration by Boreal peatlands (Intergovernmental  
25  
26 11 Panel on Climate Change (IPCC) 2014; Gorham, 1991). As such, understanding the short-term  
27  
28 12 *NEE* response of BP peatlands to forest disturbances in the context of climate variability is  
29  
30 13 essential to facilitate effective predictions of the long-term fate of these large carbon stores. Due  
31  
32 14 to the large area of the BP covered by peatlands, establishing the relationships between clear-cut  
33  
34 15 logging, peatland hydroclimate and *NEE* at the peatland-scale could provide the means to  
35  
36 16 simplify and extrapolate the carbon functioning of these ecosystems to the landscape-scale and  
37  
38 17 generalize peatland responses to disturbance by monitoring clear-cut areas across the eco-region.  
39  
40 18 As such, the objectives of this study were to examine: (1) *NEE* of BP peatlands during the snow-  
41  
42 19 free period; (2) the relative impact of upland clear-cut logging on adjacent peatland *NEE*,  
43  
44 20 including the hydrologic and microclimatological controls on this exchange; and (3) estimate the  
45  
46 21 sustainability of BP peatlands' functionality as a CO<sub>2</sub> source or sink in context of periodic land  
47  
48 22 use disturbances and climate change.

23 **Methods**

## 1 Site Description

2 Two adjacent forested-peatlands, one with an intact adjacent forested upland (I-U) and one with  
3 a harvested upland (H-U), were examined in this study located in the Utikuma Region Study  
4 Area (URSA) near Utikuma Lake, north-central Alberta, Canada (56° 20'N, 115° 30' W; Figure  
5 1). The two complexes are located on a disintegration ice moraine landform (Paulen *et al.*, 2004),  
6 within the Central Mixedwood Natural sub-region of the Boreal Forest in Alberta (Natural  
7 Regions Committee 2006) or Mid-Boreal Uplands Ecoregion of the Boreal Plains Ecozone  
8 Alberta, Canada (Ecological Stratification Working Group 1996). The climate in this region is  
9 characterized by short, warm summers and long, cold winters with a 30-year average annual  
10 temperature, precipitation and potential evapotranspiration (PET) for the region as 1.7 °C, 485  
11 mm and 515 mm, respectively (Environment Canada, 2007). The mean annual temperature and  
12 precipitation at the study site for 2005, 2006, 2007 and 2008 were 2.5, 2.5, 1.5 and 0.9 °C and  
13 491, 432, 530 and 504 mm, respectively making the study period slightly warmer and drier  
14 during pre-harvest and slightly cooler and wetter post-harvest than the 30-year normal. The  
15 prevailing wind direction across the study sites was from the South during the four-year study  
16 period (Supporting Information S1).

17 The two peatlands surround shallow ponds (< 1 m depth) and are adjacent to hillslopes with  
18 aspen-dominated uplands (up to 7 m above the pond surface) with a canopy height of  
19 approximately 17 m to 21 m on average (Brown *et al.*, 2013) and canopy coverage averaging  
20 68% (Chasmer *et al.*, 2010). The peatlands and shallow ponds are located in a recharge zone, and  
21 water tables typically grade away from the peatlands into the hillslope (Ferone and Devito, 2004;  
22 Redding and Devito, 2008). Vegetation in the peatlands are comparable, composed of a shrub  
23 layer comprising mostly *Ledum groenlandicum*, *Vaccinium vitisidaea* and *Chamaedaphne*

1 *calyculata* as well as groundcover dominated by bryophyte and lichen species characteristic of  
2 poor fen communities, mainly *Sphagnum* species and feather mosses (Solondz *et al.*, 2008;  
3 Petrone *et al.*, 2011). A similar open canopy of black spruce (canopy coverage averaging 36 to  
4 60% (Chasmer *et al.*, 2010)), approximately 2 m in height, occurs within these peatlands. Peat  
5 physical characteristics (e.g. bulk density, hydraulic conductivity) do not differ between the  
6 peatlands (Petrone *et al.*, 2008). Minimal peat subsidence occurs at these sites and does not  
7 readily respond to water level changes in the peat or adjacent ponds (Petrone *et al.*, 2008).

#### 8 *CO<sub>2</sub> Field Measurements*

9 Chamber CO<sub>2</sub> data was collected at ten sites within the harvested-upland (H-U) peatland and six  
10 in the intact-upland (I-U) peatland over the four snow-free seasons (Figure 1). At each site 20 cm  
11 (diameter) polyvinylchloride (PVC) collars were placed in adjacent lawns (classified as  
12 topographically high mounds) and depressions (low lying areas) to capture the range of  
13 microtopography in the peatlands and associated differences in CO<sub>2</sub> exchange (Petrone *et al.*,  
14 2011). CO<sub>2</sub> exchange was measured using a dynamic closed chamber system with an Infrared  
15 Gas Analyzer (IRGA) (EGM-4, PP Systems, Maryland, USA) (Solondz *et al.*, 2008). Removable  
16 clear lexan chambers were fitted to the permanently installed collars, with coolant tubes and fans  
17 operating to mimic ambient air temperatures and gradients (Solondz *et al.*, 2008; Welles *et al.*,  
18 2001). For each sample, concentrations of CO<sub>2</sub> ppm were measured at 30 second intervals for 2.5  
19 minutes during 0900-1600 h approximately ten times per month each season. Sampling times at  
20 each location were randomly selected during each sampling day to ensure measurements were  
21 taken over a wide range of light and temperature regimes that may occur throughout the day.  
22 Chambers were covered with an opaque neoprene shroud when measuring the gross respiration  
23 ( $R_{\text{tot}}$  = autotrophic and heterotrophic). Gross ecosystem productivity (*GEP*) was calculated as the

1 difference between  $NEE$  and  $R_{tot}$ ,

$$2 \quad GEP = NEE - R_{tot} \quad (1)$$

3 Negative values indicate a net  $CO_2$  uptake by the peatland, and positive values indicate a net  $CO_2$   
4 release by respiration into the atmosphere.

#### 5 *Environmental parameters*

6 Air ( $T_a$ ) temperature and relative humidity ( $RH$ ) (PP Systems, Maryland, USA), soil ( $T_{soil}$ )  
7 temperatures (Omega Engineering, Inc., Connecticut, USA) and photosynthetically active  
8 radiation ( $PAR$ ) (Quantum Sensor; LiCor Inc., Nebraska, USA) were recorded at the same  
9 temporal and spatial scales as the  $CO_2$  fluxes.  $T_a$ ,  $RH$  and  $PAR$  were measured both inside and  
10 outside of the chamber at approximately 0.5 m above the surface during each 2.5-min chamber  
11 measurement. Soil ( $T_{soil}$ ) temperatures were measured at 2, 5, and 10 cm depths and averaged for  
12 the values at the three depths.  $VMC$  was measured beside each collar using time domain  
13 reflectometry (TDR) (Hydrosense Probe, Campbell Scientific, Inc, Utah, USA) to give a bulk  
14 soil moisture value over the top 10 cm of the soil profile. The TDR was calibrated in the lab by  
15 drying representative undisturbed peat samples to different moisture contents (Solondz *et al.*,  
16 2008). The field point measurements were applied to the chamber  $CO_2$  measurements to  
17 determine the modeling of  $GEP$  and  $R_{tot}$ . Water Table depth ( $WT$ ), measured in meters below the  
18 surface, was recorded weekly using PVC pipe wells (5 cm O.D.) in the peatland and upland at  
19 each I-U and H-U site (Figure 1).

20 Meteorological towers ( $MET$ ) located in each peatland (Figure 1) continuously measured  
21 environmental parameters during the snow-free period (Day of Year (DOY)): 120 to 280) of

1 each year. Average *VMC* in the upper 30 cm of the peat was recorded using water content  
2  
3 reflectrometry (CS616, Campbell Scientific Inc, Utah, USA) placed vertically in both a lawn and  
4  
5 depression. Net radiation ( $Q^*$ ) was measured at 1.5 m above the peat surface using a net  
6  
7 radiometer (NRLite, Kipp and Zonen, The Netherlands). The  $T_a$  and  $RH$  (Vaisala, Finland) were  
8  
9 measured at the same height.  $RH$  was not available at the H-U peatland mid season (DOY 201 to  
10  
11 243) in 2007 and therefore; vapour pressure deficit ( $VPD$ ) was gap filled according to a  
12  
13 regression (using all available  $VPD$  data from *MET* and manual chamber measurements during  
14  
15 the post-harvesting period) as a function of  $T_{air}$ ,  
16  
17  
18  
19  
20  
21  
22

23 
$$VPD = 0.4748e(0.075T_{air}), r^2 = 0.87 \quad (2)$$
  
24  
25

26  $T_{soil}$  was recorded at 2, 5 and 10 cm using thermocouples (Omega copper-constantin, Campbell  
27  
28 Scientific Inc, Logan, Utah, USA) in a lawn and depression. Ground heat flux ( $Q_G$ ) was  
29  
30 measured according to the calorimetric method (Halliwell and Rouse, 1987; Petrone and Rouse,  
31  
32 2000; Petrone *et al.*, 2007) using the soil temperature profile and heat capacity calculations for  
33  
34 each soil layer (2 to 5 cm and 5 to 10 cm) accounting for changes in moisture content and state  
35  
36 (Sutherland *et al.*, 2014). Published values for heat capacities of peat soils under a range of  
37  
38 moisture conditions were used in the calculation of ground heat flux ( $Q_g$ ) (Brown *et al.*, 2010;  
39  
40 Oke, 1987; Halliwell and Rouse, 1987; Petrone and Rouse, 2000; Petrone *et al.*, 2007).  
41  
42 Horizontal wind speed ( $u$ ) measurements were collected using cup anemometers (014A, Met  
43  
44 One, Oregon, USA) at 1.4 m at both the H-U and I-U sites (Figure 1).  
45  
46  
47  
48  
49  
50

51 Downstream from a surface discontinuity, such as that from a clear-cut forest to peatland, will  
52  
53 create horizontal differences in roughness lengths (Helgason and Pomeroy, 2005). Such  
54  
55 differences in momentum sinks will cause large horizontal wind variances in the peatland, which  
56  
57  
58  
59  
60

means that mean average wind speeds may not increase but will become more variable in intensity (Helgason and Pomeroy, 2012; Wharton *et al.*, 2010). Thus, horizontal turbulence intensity ( $I_u$ ) for the peatlands was calculated according to (Turnispeed *et al.*, 2003),

$$I_u = \frac{\sigma_u}{U} \quad (3)$$

where  $\sigma_u$  is the standard deviation of the mean daily horizontal wind speed ( $\text{m s}^{-1}$ ) and  $U$  is the mean of the mean daily horizontal wind speed ( $\text{m s}^{-1}$ ) for the peatlands for each year of the study period. Wharton *et al.*, (2010) suggest that this is a more reliable means of assessing changes in turbulent regimes as a result of changing surface condition than more traditional approaches based largely on the friction velocity ( $u^*$ ), which under these conditions may suggest weak turbulent conditions while actual horizontal turbulent fluxes may be large.

### Evapotranspiration

Surface conductance and aerodynamic measurements from the peatland *MET* and wind velocity stations (see section above) were utilized to estimate *ET* by applying a standardized reference Penman-Monteith equation (Chasmer *et al.*, 2011; Temesgen *et al.*, 2005; ASCE-EWRI, 2005),

$$ET = \frac{0.408\Delta(Q^* - Q_G) + \gamma \frac{900}{T_a + 273} u (e_s - e_a)}{\Delta + \gamma(1 + 0.34u)} \quad (4)$$

where *ET* is the daily evapotranspiration rate ( $\text{mm d}^{-1}$ ),  $Q^*$  is the daily net radiation ( $\text{MJ m}^{-2} \text{d}^{-1}$ ),  $Q_G$  soil heat flux ( $\text{MJ m}^{-2} \text{d}^{-1}$ ),  $T_a$  is the mean daily air temperature ( $^{\circ}\text{C}$ ),  $u$  is the mean daily wind speed ( $\text{m s}^{-1}$ ),  $e_s$  is the mean saturation vapor pressure (kPa),  $e_a$  is the actual vapor pressure (kPa),

1  
2  
3  
4 1  $\gamma$  psychrometric constant (kPa °C<sup>-1</sup>), 900 and 0.34 are constants for reference type and  
5  
6 2 calculation time (mm d<sup>-1</sup>) (Chasmer *et al.*, 2011; Fournier *et al.*, 2007; Temesgen *et al.*, 2005;  
7  
8 3 Banaszuk and Kamocki, 2008). Evaluating surface resistance ( $r_s$ ) from individual chambers  
9  
10 4 based on a Mann-Whitney Rank Sum Test showed no significant difference in  $r_s$  between the  
11  
12 5 sites before or after harvesting ( $U = 34584$ ,  $p < 0.05$ ). Further, this *ET* model approach was  
13  
14 6 validated by comparing the seasonal average evaporation rates calculated in this study with  
15  
16 7 previously published *ET* values, from combined methods of eddy covariance and Priestley–  
17  
18 8 Taylor model, at the H-U peatland in 2005 and 2006 (Brown *et al.*, 2010; Petrone *et al.*, 2007).

22  
23  
24 9 *Peatland CO<sub>2</sub> modelling*

25  
26  
27 10 At each peatland, growing season (DOY 120 to 280) CO<sub>2</sub> exchange was estimated using the field  
28  
29 11 point flux measurements of *GEP* and  $R_{tot}$  (i.e. combined lawns and depressions). The relationship  
30  
31 12 between *GEP* and *PAR* was fitted empirically using a rectangular hyperbola regression (Whiting,  
32  
33 13 1994; Waddington and Roulet, 1996),

34  
35  
36  
37 14 
$$GEP = \frac{PAR \cdot Q \cdot GP_{max}}{(PAR \cdot Q + GP_{max})} \quad (5)$$

38  
39  
40  
41 15 where *PAR* is measured μmol m<sup>2</sup> s<sup>-1</sup>, *Q* is the quantum efficiency that describes the initial slope  
42  
43 16 of the *GEP* versus *PAR* hyperbola,  $GP_{max}$  is the theoretical maximum rate of *GEP*, representing  
44  
45 17 the asymptote of the hyperbola. Ecosystem  $R_{tot}$  was modeled using a linear regression with  
46  
47 18 average  $T_{soil}$  (5 cm depth) according to,

48  
49  
50  
51 19 
$$R_{tot} = a \cdot T_{soil} + b \quad (6)$$

52  
53  
54  
55 20 where *a* and *b* are parameters fitted by least squares regression. Peatland respiration is strongly

1 correlated with 5 cm soil temperatures at these sites (Solondz *et al.*, 2008; Petrone *et al.*, 2011)  
2 and frequently observed to correlate with soil temperature in other Boreal peatlands (e.g. Bubier  
3 *et al.*, 1998). In this study,  $T_{\text{soil}}$  (5 cm depth) also showed the best overall correlation with  $R_{\text{tot}}$  of  
4 the measured environmental parameters across the four-year study and thus equation 6 was  
5 applied to each year for consistency in the model. The daily  $\text{CO}_2$  exchange was estimated over  
6 the 160-day growing season by applying equations 5 and 6 to daily average  $PAR$  and  $T_{\text{soil}}$   
7 measurements collected from the *MET* stations at each peatland (see Figure 1) in 2005 through  
8 2008. Although variability in  $VMC$  within peatlands may influence  $T_{\text{soil}}$ , there was a general  
9 agreement between  $T_{\text{soil}}$  and  $VMC$  measured at the *MET* stations (i.e.  $T_{\text{soil}}$  used for  $R_{\text{tot}}$  modeling)  
10 with  $T_{\text{soil}}$  and  $VMC$  measurements at the chamber sites (Figure S2a and S2b). As such, *MET*  
11 station  $T_{\text{soil}}$  and  $VMC$  were used when analyzing temperature and moisture conditions between  
12 years and study sites. With the aim of highlighting differences between peatlands and the  
13 response to disturbance (rather than quantifying the exact carbon budgets), modeled  $GEP$  and  
14  $R_{\text{tot}}$  parameters described the field point flux measurements fairly well for most sampling years  
15 (Table 1) and were comparable to scatter in  $GEP$  and  $R_{\text{tot}}$  models previously reported (e.g.  
16 Bubier *et al.*, 1998; Lafleur, 1999; Petrone *et al.*, 2011; Strack *et al.*, 2014). Residuals from the  
17 regressions showed no systematic bias thus, the NEE models did not over- or under- estimate the  
18 effect of the harvesting treatment. Uncertainty estimates for NEE were assessed by assigning  
19 regression standard errors for the different models used each year.

## 20 *Statistical analyses*

21 Microclimatological and carbon exchange rate ( $NEE$ ,  $GEP$  and  $R_{\text{tot}}$ ) differences between the two  
22 peatlands (i.e. I-U versus H-U) were analyzed using Kruskal-Wallis One-Way analysis of  
23 variance (ANOVA) on Ranks and *post hoc* Tukey Test (TT), and within each peatland using

1  
2  
3 1 Friedman Repeated Measures on ANOVA on Ranks and TT over the four-year study between  
4  
5 2 day of year (DOY) 201 to 243 (i.e. mid-season) due to missing microclimatological data outside  
6  
7 3 this period in some years. Microclimatological parameters with unequal sample sizes within this  
8  
9 4 time period were analyzed using Kruskal-Wallis One-Way ANOVA and *post hoc* test Dunn's  
10  
11 5 Method (DM). Variations in *NEE*, *GEP* and  $R_{\text{tot}}$  (all available data for each year) were plotted  
12  
13 6 against each environmental parameter to isolate relationships.  
14  
15  
16  
17

18 **RESULTS**  
19

20 *Climate and environmental variables*  
21  
22  
23

24  
25 9 Minimum variability in the *WT* of the H-U peatland occurred between years, whereby median  
26  
27 10 *WT* ranged from only 11 to 16 cm depth below surface (DBS) between the pre- and post-  
28  
29 11 harvesting period (Figure 2). Despite relatively small *WT* fluctuations, large inter-annual  
30  
31 12 variability in peatland volumetric moisture content (*VMC*) was measured. During pre-harvesting  
32  
33 13 (2005 and 2006), median peatland *VMC* was high ( $0.69$  and  $0.52 \text{ m}^3 \text{ m}^{-3}$ , respectively) and  
34  
35 14 responsive to precipitation events (i.e. increase *VMC*; Figure 2). However, post-harvesting (2007  
36  
37 15 and 2008) peatland *VMC* showed a consistent seasonal decline, despite greater and more evenly  
38  
39 16 distributed precipitation. Median *VMC* in 2007 and 2008 was  $0.43$  and  $0.47 \text{ m}^3 \text{ m}^{-3}$ , respectively  
40  
41 17 and did not respond as strongly to precipitation events compared to the pre-harvesting years. In  
42  
43 18 contrast to the H-U peatland, *WT* variability of the I-U peatland was much greater (Figure 2),  
44  
45 19 where median *WT* ranged from 38 to 18 cm DBS across the four years. Although *WT*  
46  
47 20 fluctuations were relatively large, variability in peatland *VMC* was minimal ( $0.24$  to  $0.26 \text{ m}^3 \text{ m}^{-3}$ )  
48  
49 21 <sup>3</sup>). Overall, *VMC* at the I-U peatland was significantly different from the H-U peatland [ $H =$   
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1 130.806, d.f. = 6,  $p < 0.001$ ], with consistently lower [*post hoc* test (DM),  $p < 0.05$ ] median *VMC*  
 2 in both the pre- and post-harvest periods.

3  $T_{soil}$  at the H-U peatland was most similar to  $T_a$  during the late growing season of the post-  
 4 harvesting years only (2007 and 2008) when soil moisture declined to its lowest values (i.e. *VMC*  
 5  $< 0.45 \text{ m}^3 \text{ m}^{-3}$ ; Figure 3). In contrast, at the drier I-U peatland, a relatively stronger relationship  
 6 between  $T_{soil}$  and  $T_a$  was observed across years (i.e.  $T_{soil}$  approximately equal to  $T_a$ ).  $T_a$  was  
 7 similar between sites, with differences in median  $T_a$  varying  $< 3^\circ\text{C}$  during each year and showing  
 8 minimal changes in each peatland between years (i.e.  $< 6^\circ\text{C}$ ). Similarly, minimal differences in  
 9 median photosynthetic active radiation (*PAR*) were observed between peatlands (i.e.  $< 2 \text{ W m}^{-2}$ )  
 10 and within each peatlands (i.e.  $< 40 \text{ W m}^{-2}$ ) across the four-year study period (Figure S3).

11 Significant differences in vapour pressure deficit (*VPD*) occurred at the H-U peatland [ $H =$   
 12 94.520, d.f. = 3,  $p < 0.001$ ] across years (Figure 4a). Pre-harvesting (2005 and 2006) median  
 13 *VPD* was 0.37 and 0.82 kPa, respectively, and did not differ significantly [ $H = 151.730$ , d.f. = 7,  
 14  $p < 0.001$ , *post hoc* test (DM),  $p < 0.05$ ] from *VPD* at the I-U peatland. However, post-harvesting  
 15 (2007 and 2008), median *VPD* increased [*post hoc* test (DM),  $p < 0.05$ ] to 1.53 and 1.62 kPa,  
 16 respectively, and was significantly different [*post hoc* test (DM),  $p < 0.05$ ] from the I-U peatland.  
 17 The largest seasonal fluctuations in *VPD* and the highest recorded *VPD* (i.e.  $> 2 \text{ kPa}$ ) were  
 18 measured at the H-U peatland in the post-harvesting years. In contrast, median *VPD* at the I-U  
 19 peatland remained low (i.e.  $\leq 0.79 \text{ kPa}$ ) during each year of the study. Wind speed at the H-U  
 20 site significantly differed across years [ $\chi^2(3) = 39.921$ ,  $p < 0.001$ ] (Figure 4b); however, *post hoc*  
 21 tests (TT) showed that wind speed (2007) did not significantly differ from pre-harvesting (2005).  
 22 Median wind speed at the H-U site varied from 0.8 to 1.4  $\text{m s}^{-1}$  across years, and showed similar  
 23 variability to wind speed at the I-U site (median 1.1 to 1.6  $\text{m s}^{-1}$ ). Despite minimal changes in

1 wind speed, turbulence intensity ( $I_u$ ) at the H-U site increased post-harvesting from 0.26 and 0.38  
 2 in 2005 and 2006 to 0.60 and 0.52 in 2007 and 2008, respectively (Figure 4b). In contrast,  $I_u$   
 3 remained low at the I-U site across years, ranging from 0.24 to 0.34. Significant differences in  
 4  $ET$  [ $H = 79.355$ , d.f. = 3,  $p < 0.001$ ] occurred at the H-U peatland across the four-years (Figure  
 5 4c). Similar to peatland VDP, *post hoc* tests (DM) showed  $ET$  was significantly different ( $p <$   
 6 0.05) between pre- and post-harvesting years. Although  $ET$  also significantly increased [ $H =$   
 7 15.892, d.f. = 3,  $p < 0.001$ , *post hoc* tests (DM),  $p < 0.05$ ] at the I-U peatland in 2008 compared  
 8 to 2005, overall larger increases in  $ET$  occurred at the H-U peatland between the pre- and post-  
 9 harvesting years, whereby median  $ET$  increased from 1.4 and 2.0 mm d<sup>-1</sup> in 2005 and 2006 to 3.4  
 10 and 4.3 mm d<sup>-1</sup> in 2007 and 2008, respectively.

#### 11 *Seasonal variation in peatland carbon exchange*

12 During the pre-harvesting period (2005 and 2006), inter-annual variability of  $NEE$  between  
 13 peatlands and within each peatland was low (Figure 5).  $NEE$  rates at the H-U peatland were  
 14 consistently lower (i.e. greater carbon uptake) and significantly different [ $H = 285.517$ , d.f. = 7,  
 15 *post hoc* test (TT),  $p < 0.05$ ] from  $NEE$  at the I-U peatland. The H-U peatland fluctuated between  
 16 a slight carbon source and carbon sink (median 0.52 and -0.03 g CO<sub>2</sub>-C m<sup>-2</sup> d<sup>-1</sup> in 2005 and 2006,  
 17 respectively) while the I-U peatland functioned as a consistent slight carbon source (median 1.30  
 18 and 1.65 g CO<sub>2</sub>-C m<sup>-2</sup> d<sup>-1</sup> in 2005 and 2006, respectively) (Figure 5). Pre-harvesting  $R_{tot}$  was  
 19 lower at the H-U peatland (median 5.28 and 7.96 g CO<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup> in 2005 and 2006, respectively)  
 20 and significantly different [ $H = 282.365$ , d.f. = 7, *post hoc* test (TT),  $p < 0.05$ ] from the I-U  
 21 peatland (median 10.12 and 12.10 g CO<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup> in 2005 and 2006, respectively; Figure 6a). In  
 22 contrast,  $GEP$  was slightly higher at the H-U peatland in 2005 and 2006 (median 3.72 and 8.18 g  
 23 CO<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>, respectively) from the I-U peatland (median 2.03 and 6.27 g CO<sub>2</sub> m<sup>-2</sup> d<sup>-1</sup>,

respectively) but did not significantly differ [ $H = 282.520$ , d.f. = 7, *post hoc* test (TT),  $p < 0.05$ ] between peatlands (Figure 6b).

One year post-harvesting (2007), both peatlands functioned as a net carbon sink from the atmosphere at the beginning of the season and showed a steady decline in carbon uptake (i.e. higher *NEE*) towards mid-season (Figure 5). *NEE* rates were lower (i.e. greater carbon uptake) and significantly different [H-U peatland,  $\chi^2(3) = 91.660$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ; I-U peatland,  $\chi^2(3) = 99.865$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from *NEE* in the pre-harvesting years at both peatlands. The H-U peatland functioned as a consistent net carbon sink from the atmosphere (median  $-1.34 \text{ g CO}_2\text{-C m}^{-2} \text{ d}^{-1}$ ) and significantly differed [ $H = 285.517$ , d.f. = 7,  $p < 0.001$ , *post hoc* test (TT)  $p < 0.05$ ] from *NEE* at the I-U peatland, which was a consistent net carbon source (median  $0.62 \text{ g CO}_2\text{-C m}^{-2} \text{ d}^{-1}$ ).  $R_{\text{tot}}$  at the H-U peatland was lower (median  $5.83 \text{ g CO}_2\text{-C m}^{-2} \text{ d}^{-1}$ ) and significantly different [ $\chi^2(3) = 118.619$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from 2006, but did not significantly differ [*post hoc* test (TT),  $p < 0.05$ ] from 2005 (Figure 6a). No significant change [ $\chi^2(3) = 70.898$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] in  $R_{\text{tot}}$  (median  $10.89 \text{ g CO}_2\text{-C m}^{-2} \text{ d}^{-1}$ ) occurred at the I-U peatland relative to 2005 or 2006. Consistent with trends of the pre-harvesting period,  $R_{\text{tot}}$  at the H-U peatland was lower and significantly different [ $H = 282.365$ , d.f. = 7, *post hoc* test (TT),  $p < 0.05$ ] from the I-U peatland. *GEP* increased within both peatlands and significantly differed [H-U peatland,  $\chi^2(3) = 100.033$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ; I-U peatland,  $\chi^2(3) = 104.526$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from 2005 and 2006 (Figure 6b). Similar to pre-harvesting, *GEP* at the H-U peatland remained slightly higher (median  $10.63 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ ) but was not significantly different [ $H = 282.520$ , d.f. = 7, *post hoc* test (TT)  $p < 0.05$ ] from the I-U peatland in 2007 (median  $9.01 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ ).

Two years post-harvesting (2008), both peatlands showed a steady decline in net carbon uptake from the beginning to mid-season (Figure 5). *NEE* at the H-U peatland still remained lower (median  $0.18 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ ) and significantly different [H-U peatland,  $\chi^2(3) = 91.660$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from *NEE* in 2005, however, was no longer significantly different [*post hoc* test (TT)  $p < 0.05$ ] from 2006. In contrast, *NEE* at the I-U peatland was higher (median  $2.67 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ ) and significantly different [ $\chi^2(3) = 99.865$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from 2005 and 2006. *NEE* at the I-U peatland was significantly different [ $H = 285.517$ , d.f. = 7, *post hoc* test (TT),  $p < 0.05$ ] from the H-U peatland in 2008, showing the greatest net carbon release from either site observed over the four-year study period.  $R_{\text{tot}}$  in both peatlands significantly differed [H-U peatland,  $\chi^2(3) = 118.619$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ; I-U peatland,  $\chi^2(3) = 70.898$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from the pre-harvesting years (2005 and 2006; Figure 6a). Although the highest  $R_{\text{tot}}$  was observed in both peatlands during 2008,  $R_{\text{tot}}$  at the H-U peatland ( $11.92 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ ) still remained lower and significantly different [ $H = 282.365$ , d.f. = 7, *post hoc* test (TT),  $p < 0.05$ ] from the I-U peatland ( $15.98 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ ). *GEP* in both peatlands increased and were significantly different [H-U peatland,  $\chi^2(3) = 100.033$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ; I-U peatland,  $\chi^2(3) = 104.526$ ,  $p < 0.001$ , *post hoc* test (TT),  $p < 0.05$ ] from 2005 and 2006 (Figure 6b). *GEP* was significantly higher [ $H = 282.520$ , d.f. = 7, *post hoc* test (TT),  $p < 0.05$ ] at the H-U peatland relative to the I-U peatland (median *GEP* = 11.69 and 6.73  $\text{g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ , respectively; Figure 6b).

Despite large degree of uncertainty in the peatland *NEE* models, the scatter is typical of  $\text{CO}_2$  flux models reported in other studies (e.g. Bubier *et al.*, 1998; Lafleur, 1999; Petrone *et al.*, 2011; Strack *et al.*, 2014). Mean standard errors for the *NEE* models ranged from  $\pm 0.73$  to  $1.6 \text{ g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ . Although the uncertainty for the models (i.e. maximum and minimum estimates)

overlapped during the undisturbed period, the overall discrepancy in *NEE* between peatlands remained large after harvesting; therefore the interpretation of shifts in  $\text{CO}_2$  exchange at the H-U peatland relative to the I-U peatland due to disturbance remains valid.

#### *Hydroclimatic influence on peatland carbon exchange*

*NEE* at the H-U peatland correlated well with changes in *VMC* during the post-harvesting period only (Figure 7a). Greater net carbon uptake (i.e. lower *NEE*) with increasing peatland soil moisture occurred in 2007 and 2008. In contrast, poor relationships between peatland *NEE* and *VMC* were observed during pre-harvesting (2005 or 2006). Minimal variability in *VMC* at the I-U peatland within growing seasons and across the study period resulted in no relationship between peatland *NEE* and *VMC* at the I-U site and as such, was not shown in Figure 7.

The distinct relationship between *NEE* and *VMC* at the H-U peatland in 2007 and 2008 reflected strong moisture linkages with *GEP* and  $R_{\text{tot}}$  (Figure 7b and 7c). For example, *GEP* in the H-U peatland increased with higher *VMC* (i.e. greater productivity with soil moisture) in 2006 to 2008 (Figure 7b). The strongest relationships between *GEP* and *VMC* occurred during the post-harvesting years (2007 and 2008). No correlation between *GEP* and *VMC* was observed in 2005. Similar to *GEP*,  $R_{\text{tot}}$  in the H-U peatland also correlated with *VMC*; however, the relationship only occurred during the post-harvesting years (2007 and 2008) and was seasonally dependent (Figure 7c). For example, during the early growing season of 2007 and 2008,  $R_{\text{tot}}$  showed a strong quadratic relationship with *VMC* peaking at 7.4 and 4.3  $\text{g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$ , respectively, when the peatland soil was generally wet (Figure 2) and cool (Figure 3). By the end of the growing seasons, maximum  $R_{\text{tot}}$  peaked higher at 12.5 and 6.8  $\text{g CO}_2 \text{ m}^{-2} \text{ d}^{-1}$  in 2007 and 2008, respectively when the peatland soil was generally dry and relatively warmer.

1     **Discussion**

2     *Natural variability in BP peatland carbon dynamics*

3     Throughout the study period, the H-U peatland functioned mainly as a net carbon sink while the  
4     I-U peatland was frequently a small net source. *NEE* rates in both peatlands ranged from -1.51 to  
5     2.12 g CO<sub>2</sub>-C m<sup>-2</sup> d<sup>-1</sup> during the undisturbed pre-harvest period (2005 and 2006) and were  
6     comparable to previous reports of natural *NEE* rates in Boreal peatlands (e.g. Bellisario *et al.*,  
7     1998; Shurpali *et al.*, 1995; Humphreys *et al.*, 2006).

8     Differences in *NEE* between the H-U and I-U peatlands during the undisturbed period indicates  
9     the potential for large natural variability in carbon cycling of peatlands on the Boreal Plains  
10    (BP), even peatlands in relatively close proximity to each other as observed in this study (i.e. < 1  
11    Km distance). Higher inter-annual *R*<sub>tot</sub> and frequently larger seasonal variability in *R*<sub>tot</sub> at the I-U  
12    peatland relative to the H-U peatland likely reflected the consistently drier (i.e. lower water table  
13    and soil moisture) and warmer soils at that site. Greater CO<sub>2</sub> release has been observed under  
14    lower water table positions in both laboratory settings (Moore and Dalva, 1993; Van de Reit et  
15    al., 2013) and in situ studies (Silvola *et al.*, 1996; Kim and Verma, 1992; Gažovič *et al.*, 2013;  
16    Helfter *et al.*, 2015). Further, changes in peat temperature can alter decomposition rates and CO<sub>2</sub>  
17    emissions (Waddington *et al.*, 2001) whereby even minor soil temperature increases in high  
18    quality soils can provide optimal conditions for decomposition, thus increasing respiration  
19    (Solondz *et al.*, 2008).

20    Soil moisture is also an important factor influencing peatland *Sphagnum* productivity (McNeil  
21    and Waddington. 2003), as was reflected by the slightly higher *GEP* at the wetter H-U peatland  
22    that contributed to the overall lower *NEE* (i.e. greater net carbon uptake) during the undistributed

1 period. However, despite *WT* and soil *VMC* being low and disconnected at the I-U peatland,  
2 maintenance of a sufficient water supply by dew or precipitation as well as moisture retention by  
3 the moss (Strack and Price, 2009) may have moderated the impact of low soil water availability  
4 on moss carbon uptake. This will maintain a relatively productive moss cover at the I-U peatland  
5 (i.e. median *GEP* at the I-U peatland was 54% to 76% of median *GEP* at H-U peatland).  
6 Together, differences in *NEE* linked to natural variations in site hydrology suggest the potential  
7 for spatially variable seasonal and inter-annual carbon exchange of peatlands on the BP,  
8 consistent with previous studies reporting soil moisture controls on CO<sub>2</sub> balances in peatlands  
9 (Lafleur *et al.*, 2001; Strack *et al.*, 2009; Trudeau *et al.*, 2014). Therefore, assessing potential  
10 impacts of land use disturbances on *NEE* of BP peatlands requires careful consideration of site-  
11 specific natural variability in water availability influencing respiration and productivity across  
12 this eco-region.

### 13 *Impact of forest harvesting on peatland hydroclimatic and carbon exchange*

14 Shifts in peatland microclimate at the H-U site post-harvest may have reflected the loss of a  
15 protective sheltering effect created by the adjacent upland forest (Chen *et al.*, 1993). Post-  
16 harvesting, higher vapour pressure deficit (*VPD*) measured in the newly exposed H-U peatland  
17 may have resulted from decreased stability of the surface boundary layer and increased mixing  
18 with the upper atmosphere due to an increase in fetch within the newly formed adjacent cutblock.  
19 Dynamic turbulent flow patterns occur across landscape transitions (e.g. Markfort *et al.*, 2014;  
20 Yang *et al.*, 2006; Flesch and Wilson, 1999). Although significant increases in wind speed were  
21 not observed in the H-U peatland after harvesting, wind speeds are expected to be more variable  
22 and turbulence increase with an increased momentum sink over the peatland relative to the clear-  
23 cut forested area (Helgason and Pomeroy, 2005; Helgason and Pomeroy, 2012; Turnispeed *et al.*,

1  
2  
3 1 2003), likely contributing towards higher peatland *VPD* and *ET* (Petrone *et al.*, 2007). Even  
4  
5 2 slight shifts in *ET* can alter the water balance of a peatland in this water deficit eco-region, given  
6  
7 3 that *ET* is the dominant component of peatland water budgets on the BP (Devito *et al.*, 2005;  
8  
9 4 Ferone and Devito, 2004; Smerdon *et al.*, 2005). As such, the greater evaporative water loss in  
10  
11 5 the H-U peatland post-harvesting may have contributed to the seasonal decline of peatland *VMC*  
12  
13 6 at that site, despite a relatively consistent supply of precipitation and overall wetter conditions in  
14  
15 7 2007 and 2008.  
16  
17  
18  
19  
20  
21 8 Post-harvesting, *VMC* became a limiting control on *NEE* at the H-U peatland, as indicated by the  
22  
23 9 strong relationship with peatland *NEE* occurring in 2007 and 2008 only. Moisture conditions are  
24  
25 10 frequently well correlated with both carbon losses (plant respiration and soil decomposition) and  
26  
27 11 carbon fixation (plant production) (Davidson *et al.*, 2000; Bubier *et al.*, 2003). Although the  
28  
29 12 overall range of soil *VMC* was similar in each year of the four-year study period (~0.40 to 0.70  
30  
31 13 m<sup>3</sup> m<sup>-3</sup>), the timing of moisture loss (i.e. consistent seasonal decline) appeared critical to  
32  
33 14 influencing seasonal patterns of respiration and productivity during the post-harvesting period.  
34  
35 15 For example, low *VMC* near the end of the 2007 and 2008 growing seasons corresponded with  
36  
37 16 the warmest soil temperatures and thus, contributed to higher *R<sub>tot</sub>* (i.e. greater carbon release to  
38  
39 17 the atmosphere) relative to the wetter cool soils at the beginning of the season. In contrast,  
40  
41 18 frequent re-wetting by precipitation events during the pre-harvesting period resulted in no  
42  
43 19 seasonal trend between *VMC*, *T<sub>soil</sub>* and *R<sub>tot</sub>* in 2005 and 2006.  
44  
45  
46  
47  
48  
49  
50 20 Strong correlations between increasing *GEP* and increasing *VMC* were observed at the H-U  
51  
52 21 peatland from 2006 to 2008. The lack of a relationship between *GEP* and *VMC* in 2005 likely  
53  
54 22 reflected the predominantly high moisture conditions that year. The strongest relationship  
55  
56 23 between *GEP* and *VMC*, as well as higher *GEP* for a given *VMC* (i.e. more efficient carbon  
57  
58  
59  
60

uptake), occurred during the post-harvesting years, likely reflecting the coinciding timing of high soil *VMC* and peak *PAR* during that period. For example, the highest *GEP* occurred during the beginning and mid-season, corresponding to the highest *VMC* and near maximum *PAR*, thus contributed toward the large net carbon accumulation. In contrast, lower *GEP* during pre-harvesting may reflect that the highest *VMC* occurred later in the growing season when *PAR* was generally lower. Consistent with our results, Griffis *et al.*, (2000) found that large carbon accumulation in a subarctic fen was the result of wetter conditions and early snowmelt during the warm spring period, even when drier conditions persisted for the majority of the growing season.

#### *Implications for land use management on the Boreal Plains*

BP peatlands exist in a moisture deficit region, and are in a state of hydrologic risk. Results of this study indicate the importance of soil moisture influencing peatland productivity and respiration. Thus, any land-use disturbances impacting peatland water availability, such as changes to peatland microclimate observed in this study, are likely to have a direct influence on the  $\text{CO}_2$  exchange of BP peatlands. Large inter-annual variability in  $\text{CO}_2$  exchange is common in northern peatlands (e.g. Aurela *et al.*, 2009), including shifts between a net  $\text{CO}_2$  sink and source due to natural variations in hydrological and microclimatic conditions (Joiner *et al.*, 1999; Shurpali *et al.*, 1995; Lund *et al.*, 2012). In this study, shifts in mid-season *NEE* one-year post-harvesting were greater than the natural *NEE* variability of the pre-harvesting period at both peatlands. However, a larger relative change in *NEE* (i.e. greater net carbon uptake) occurred at the H-U site after forest removal. This suggests clear-cut logging may modify adjacent peatland microclimates and soil moisture conditions to influence *GEP* and  $R_{\text{tot}}$  in the short-term. However, given that mid-season *NEE* returned to within the range of the pre-harvest period two years post-harvesting suggests the relatively small-scale clear cutblock in this study may not sufficiently

1  
2  
3 1 alter *NEE* outside that of natural variation due to climate and/or site hydrology and/or  
4  
5 2 microclimatic conditions. As such, the long-term carbon exchange function of BP peatlands may  
6  
7 3 largely be influenced by changes in water availability resulting from drier conditions expected by  
8  
9 4 future climate warming (IPCC, 2014). However, careful consideration of larger-scale logging  
10  
11 5 due to rapid expansion of deforestation across this region (Timoney, 2003) may compound  
12  
13 6 anticipated drought conditions induced by climate change. In particular, consideration of forest  
14  
15 7 cutblock size (e.g. Flesch and Wilson, 1999) as well as orientation of cutblocks relative to the  
16  
17 8 dominant wind direction may enhance alterations to adjacent peatland hydroclimatic conditions  
18  
19 9 and CO<sub>2</sub> exchange dynamics and thus, impact stability of BP peatland water supply and carbon  
20  
21 10 stores.  
22  
23  
24  
25  
26  
27

28 11 **Conclusion**

29  
30  
31 12 Peatland growing season ecosystem CO<sub>2</sub> exchange data suggest the potential for large variability  
32  
33 13 in carbon cycling of undisturbed peatlands on the BP linked to natural hydrologic differences  
34  
35 14 between sites (i.e. higher  $R_{\text{tot}}$  and *NEE* in the naturally drier peatland). The changes to peatland  
36  
37 15 moisture soil conditions, linked to alterations in microclimate (i.e. increased turbulent mixing,  
38  
39 16 vapour pressure deficit and evapotranspiration) by adjacent upland clear-cut logging, shifted  
40  
41 17 peatland respiration and productivity patterns and thus, demonstrate that utilizing an integrated  
42  
43 18 hydrometeorological approach is fundamental to ecosystem monitoring as well as designing  
44  
45 19 landscape management and forestry strategies for the protection of BP peatland ecosystem  
46  
47 20 function. The results of short-term alterations to peatland hydroclimatic and carbon exchange  
48  
49 21 dynamics by clear-cut logging indicates that in addition to climate change, the sustainability of  
50  
51 22 BP peatlands ecosystem function may also depend on periodic forest disturbances expected with  
52  
53 23 the rapid expansion of deforestation, while the particular peatland response is likely to be site-  
54  
55  
56  
57  
58  
59  
60

specific due to natural variability in terrestrial-atmosphere exchange of water and CO<sub>2</sub> within these hydrologically tenuous ecosystems in this moisture deficit region.
